ABSTRACT

Flow prediction and measurement were performed to clarify swirl chamber flow in diesel engines. A flow model is based on the solution of the finite difference form of the governing differential equations for the transport of mass, momentum, kinetic energy of turbulence, and its dissipation rate. Simulations have been made using flow models for the three kinds of swirl chambers with different connecting passages. Before predicting swirl chamber flow, the flow model was confirmed in experiments using an air model. Then flow characteristics in the swirl chamber of a full scale engine were predicted. Swirl chamber geometry was found to extensively influence basic flow characteristics, such as tangential velocity and turbulence intensity.

INTRODUCTION

Air flow in the swirl chamber of diesel engines greatly influences the fuel-air mixing and combustion processes. They also affect noise emission and the formation of pollutants such as soot and nitrous oxides. Swirl produced during compression has great influence on mixture formation and subsequent combustion. Air flow during expansion stroke is also important in that it ensures final air utilization in the main chamber. Numerous efforts have therefore been made to clarify swirl chamber flow characteristics. However, many results are not quantitative but qualitative, resulting in a limited understanding at present.

To arrive at a better understanding, a flow prediction method should be established using the modern computer prediction method developed by the following investigators. Gosman and his co-workers (1) and Ramos et al (2) solved flows in the engine cylinder using the finite difference method. Elkotb et al (3) used this same technique to assess swirl chamber flow in diesel engines. Several three-dimensional simulations have been presented recently by Ikegami and his coworkers (4), Nishiwaki et al (5), and Wakisaka et al (6). Their results suggested that the method is suitable for predicting swirl production.

In this study, the authors aimed to understand swirl chamber flow using a similar approach.

Special emphasis was placed on the effects of swirl chamber geometry and the connecting passage. To elucidate combustion in the later crank angles, swirl motion during the expansion stroke was also studied. The k-ε model parameters proposed by Jones and Launder (7) were used in prediction method. Before predicting swirling flow in an actual engine, numerical prediction results were comfirmed in experments using a special air model. Finally, the effects of swirl chamber geometry on flow characteristics were examined under full-scale engine conditions.

FLOW MODEL

To facilitate flow analysis, swirl chamber flow in diesel engines was assumed to be two-dimensional and transient. Turbulent shear stress was expressed as the product of local turbulent effective viscosity and local mean rate of strain. The turbulent effective viscosity was determined according to the turbulent structure related to turbulence kinetic energy k and its dissipation rate ε. Within this framework we adopted the k-ε model proposed by Jones et al.

Flow model. Flow is described in terms of partial differential equations that govern mass continuity and momentum together with the kinetic energy of turbulence k and its dissipation rate ε. Polar coordinates (r,θ) were used. The governing set of equations may be compactly represented in terms of a single general transport equation for an arbitrary dependent variable.

$$\frac{\partial}{\partial t}(\rho\phi) + \frac{1}{r}\frac{\partial}{\partial r}(r\rho u\phi) + \frac{1}{r}\frac{\partial}{\partial\theta}(\rho v\phi) - \frac{1}{r}\frac{\partial}{\partial r}(r\Gamma\phi \frac{\partial\phi}{\partial r})$$

$$- \frac{1}{r^2}\frac{\partial}{\partial\theta}(\Gamma\phi \frac{\partial\phi}{\partial\theta}) = S\phi \qquad (1)$$

Where ϕ is radial velocity u, tangential velocity v, kinetic energy k, and its dissipation rate ε, t is time, and ρ is density, Γ_ϕ and $S\phi$ equal the turbulent effective diffusivity coefficients and source or sink terms respectively. Definitions of Γ_ϕ and S_ϕ are given in Table 1. In this Table 1, μ_{eff} equals turbulent effective viscosity;

$$\mu_{eff} = \mu + C_\mu \rho k^2 / \varepsilon \qquad (2)$$

Table 1   Definitions of coefficients appearing in general transport Eq. 1

ϕ	$\Gamma\phi$	$S\phi$
u	μ_{eff}	$-\frac{\partial p}{\partial r} + \frac{1}{r}\frac{\partial}{\partial r}(r\ \mu_{eff}\frac{\partial u}{\partial r}) + \frac{1}{r}\frac{\partial}{\partial \theta}\{\mu_{eff}(\frac{\partial v}{\partial r} - \frac{v}{r})\} + \frac{\rho v^2}{r}$ $-\frac{2\mu_{eff}}{r^2}(u + \frac{\partial v}{\partial \theta}) - \frac{2}{3r}\frac{\partial}{\partial r}\{r(\mu_{eff}\ div(V) + \rho k)\}$
v	μ_{eff}	$-\frac{1}{r}\frac{\partial p}{\partial \theta} + \frac{1}{r}\frac{\partial}{\partial r}\{r\ \mu_{eff}(\frac{1}{r}\frac{\partial u}{\partial \theta} - \frac{v}{r})\} + \frac{1}{r^2}\frac{\partial}{\partial \theta}\{\mu_{eff}(\frac{\partial v}{\partial \theta} + 2u)\}$ $+ \frac{\mu_{eff}}{r}(\frac{1}{r}\frac{\partial u}{\partial \theta} + \frac{\partial v}{\partial r}) - \mu_{eff}\frac{v}{r^2} - \rho\frac{uv}{r} - \frac{2}{3}\frac{1}{r}\frac{\partial}{\partial \theta}(\mu_{eff}\ div(V) + \rho k)$
1	0	0
k	$\frac{\mu_{eff}}{\sigma k}$	$G - C_\mu\ \rho\varepsilon$
ε	$\frac{\mu_{eff}}{\sigma\varepsilon}$	$\frac{\varepsilon}{k}(C_1G - C_2\rho\varepsilon)$

$$G = \mu_{eff}\{2(\frac{1}{r}\frac{\partial v}{\partial \theta} + \frac{u}{r})^2 + 2(\frac{\partial u}{\partial r})^2 + (\frac{1}{r}\frac{\partial u}{\partial \theta} + \frac{\partial v}{\partial r} - \frac{v}{r})^2\}$$
$$- \frac{2}{3}div(V)\{\mu_{eff}\ div(V) + \rho k\}$$

where C_μ, C_1, C_2, σ_K, σ_ε, are turbulence model constants, also given in Table 2 and μ is molecular viscosity.

The general transport equation (1) is solved using a finite difference procedure based on a semi-implicid method. The velocity field u, v is solved explicitly in time increments, after which pressure corrections are implicitly made to satisfy equation continuity. The pressure corrections are calculated using a line-by-line double sweep method. Iteration processes were repeated four times, after which the maximum normalized residual became negligible. The hybrid scheme (8) was used to overcome the difficulty encountered at a high convection rate relative to diffusion.

Boundary and initial conditions. Boundary conditions were assumed as follows. No-slip conditions were applied for velocities at walls, which are thermally insulated. The following wall function was used for grid nodes adjacent to the chamber wall. The turbulent shear stress near the wall is

$$\tau_w = \begin{cases} \frac{K\ C_\mu^{1/4}\ \rho\ v\ k^{1/2}}{\ln(E\ \rho\ y\ k^{1/2}\ \bar{\mu}^{-1})} & , y^+ = \rho\ k^{1/2}\ y\ \bar{\mu}^{-1} \geq 11.5 \\ \mu\frac{v}{y} & , y^+ < 11.5 \end{cases}$$ (3)

where K=0.4 and E=9.0 are constants of wall function and y is distance from wall. Turbulence fluctuations and their dissipation rate were assumed to be zero at the wall.

At the passage connecting the swirl chamber with the main chamber, inlet velocity and density were given for each crank angle according to piston movement.

ENGINE USED IN PREDICTION AND EXPERIMENT

Predictions for swirl chamber geometries were attempted in an engine, specifications of which are shown in Table 3.

Swirl chamber geometry. The three kinds of swirl chamber shown in Fig.1 were used. Type A is cylindrical, similar to the Ricardo Comet III type, and has a tangential connecting passage. Type B is the same as type A except that the connecting passage is offset. Type C has a flat bottom similar to the Ricardo Comet V type and a connecting passage inclined 45 degrees to the bottom surface. All swirl chambers have a diameter D_s of 37mm and a connecting passage width h_p 0.17% the diameter.

The experimental investigation. Before predicting flow in the above chamber, numerical prediction was confirmed in an experiment using a special air model. A four-cycle diesel engine was rebuilt for the air model by exchanging the cylinder head for one without intake and exhaust valves. For ease of measurement a cylindrical swirl chamber 60 mm in diameter and approximately 1.6 times the size of the original chamber was installed on the new cylinder head. One side of the chamber was made of aclyl material for visual inspection. The compression ratio was 5 : 1 The air model was powered by an electric dynamometer at 250 rpm.

Table 3 Specifications of engine used in
prediction and air model

	Engine used in prediction	Air model
Swirl chamber diameter, mm	37	60
Cylinder diameter, mm	95	150
Stroke, mm	110	110
Swirl chamber volume ratio	0.5	0.13
port area ratio	0.02	0.01
Engine speed, rpm	1800	250

To measure air velocity and its turbulence
intensity, a 12.7 µm diameter platinum hot-wire
probe was inserted into the swirl chamber.
The probe was traversed in the specified radial
direction of the chamber. In addition, a pressure
transducer was fitted to the chamber to measure
pressure as shown in Fig.2.

Hot-wire anemometry was performed under
constant temperature. Due to changes in air
temperature and density, the anemometer did not
give correct velocity. Compensation was made based
on the equation of Collis & Williams, on reading
gained at a proof-duct under atomospheric condi-
tions, and on the thermal equilibrium of the
hot-wire with the surrounding air. Turbulence
intensity was determined by an ensemble-average
method which assumes fluctuation relative to the
ensemble-average to be turbulence intensity.

PREDICTION AND EXPERIMENTAL RESULTS

Special air model. Prediction was carried
out using a special air model of swirl chamber
type A, dimensions for which are shown in Table 3.
The computational grid inside the swirl chamber
consisted of 20 angular and 10 radial locations on
polar coordinates. Computations were conducted at
the beginning of the compression stroke and carried
out at increments between 0.01 degree and 0.05
degree in crank angle.

Figure 3 shows the resulting velocity field
computed during compression and expansion stroke.
The tangential velocity at the specified locations
$\ell - \ell'$ shown in Fig.1 are shown in Fig.4. As may be
seen in Fig.3 and Fig.4, a radial flow is directed
from the connecting passage to the opposite wall at
the beginning of compression. A vortex is observed
at the left hand side near the connecting passage
at a crank angle of about 30 degrees. Later total
swirling flow builds up. The increase of inflow
to the swirl chamber produces a large tangential
velocity, which reaches maximum value at 150 deg.CA
during compression stroke, after which it decreases
slightly. This may be attributted to the decrease
of the ejected velocity from the maximum value at
about 150 deg.CA to zero value at TDC. At the end
of compression, swirl chamber flow consists of two
zones, the rigid-body vortex at the center of the
chamber and the free-vortex zone at near the wall.
The flow characteristics mentioned about during

compression stroke showed the same as that found
for previous paper (9) predicted using momentum
equation. Further, regarding swirl chamber flow
during expansion stroke, the maximum jet flow from
the chamber during expansion stroke can be seen at
about 200 deg.CA. After a time swirling flow
decreases, and reverse-swirling flow appears in a
part of the chamber at about 270 deg.CA.

The turbulence intensity I_t , defined by the
dimensionless value $\sqrt{2k/3}/Cm$, at specified loca-
tions $\ell - \ell'$ shown in Fig.1 for various crank angles
was computed and is shown in Fig.5. Where k is
turbulence kinetic energy m^2/s^2, and Cm is mean
piston velocity m/s. Turbulence intensity is very
low at the beginning of the compression stroke, as
shown in Fig.5(a). After crank angle reaches 50
degrees, intensity increases rapidly during com-
pression and at about 130 deg.CA comparatively high
turbulence intensities appear in the enter of the
chamber and near the wall, and intensities decrease
at 180 deg.CA. It is found that at 180 deg.CA a
large value can be seen near the chamber wall and
center due to high shear stresses generated in
these regions and the minimum value occurs at
nearly midway between chamber wall and center.
Moreover, as shown in Fig.5(b), turbulence inten-
sity decreases during expansion stroke except the
center of the chamber.

Experiment was performed using the special
air model of swirl chamber type A. · The comparison
was made between the experimental results and the
simulations. The measured tangential velocity at
the locations $\ell - \ell'$ shown in Fig.1 versus crank
angle during compression stroke is shown in Fig.6
(a). Being seen in Fig.6(a), as the crank angle
proceeds, the swirl velocity increases, and the
swirl becomes alike a rigid-body rotation except
the part close to the chamber wall. Decelaration
near the wall was noticed during the compression
stroke. On comparing the computed results in Fig.3
and Fig.4 with the measured values in Fig.6(a),it
may be stated that the computed tangential velocity
profiles during the compression stroke are compara-
tively good agreement with the experimental
results. However, comparing the both velocity
profiles in detail, a discrepancy was noticed
midway between the center and the wall of the
chamber at near TDC.

Further, from Fig.5 and Fig.6(b), it might be
stated that, although predicted results for turbu-
lence intensity are comparatively smaller than
experimental results, the shifting of turbulence
intensities at crank angles shows the same tendency
with both cases.

Engine used in prediction. Next, simulations
were attempted for an engine used in prediction,
specifications for which are shown in Table 3.
Computations were carried out for two types B and C
of swirl chamber shapes which might be important in
usual cases. Velocity fields computed from the
beginning of compression to the end of expansion
stroke for each swirl chamber are shown in Fig.7,
Fig.8, Fig.10 and Fig.11.

In general, formation of swirl during compre-
ssion stroke is similar to that observed in the air
model. However, some differences exist in the
profile of each swirl chamber shape. Referring to
the flow in the swirl chamber during compression
stroke, swirling flow of type C is stronger than
that of tpye B, and velocity vectors of type B
during expansion stroke are larger than that of

type C in the periphery. Specially, at 270 deg.CA, the flow in the chamber of type B increases near the passage in consequence of the ejected air flow from the chamber, while that of type C affected by the connecting passage and the bottom surface of the chamber is remarkable in the center of the chamber. At the end of the expansion stroke, the weak reverse-swirling flow is noticed in a part of the chamber with both types.

Finally, as shown in Fig.9 and Fig.12, the difference of turbulence intensity between both types can be found that the turbulence intensity of type C is comparatively larger than that of type B in the center of the chamber and near the wall during compression stroke, and the former still remains comparatively large turbulence in the center of the chamber at the end of the expansion stroke.

Computations for the above simulation were performed on FACOM M-360 computer in Himeji Institute of Technology.

CONCLUSIONS

The followings were concluded based on the predictions and experimental data obtained in this study.

1. Predicted tangential velocity and turbulence intensity qualitatively agreed with experimental results obtained using a special air model.
2. Prediction shows that during the compression stroke the turbulence intensity increases rapidly as tangential velocity increases.
3. Swirl chamber geometry greatly affectes turbulence intensity in the center of the chamber and near the wall, where turbulence intensity is strong.
4. During expansion stroke the swirl motion quickly decays, forming a reverse-swirling in the final stage.
